ABSTRACT

A modular, transdiagnostic approach to treatment design and implementation may increase the public health impact of evidence-based psychosocial interventions. Such an approach relies on algorithms for selecting and implementing treatment components intended to have a specific therapeutic effect, yet there is little evidence for how components function independent of their treatment packages when employed in clinical service settings. This study aimed to demonstrate the specificity of treatment effects for two components of Acceptance and Commitment Therapy (ACT), a promising candidate for modularization. A randomized, nonconcurrent, multiple-baseline across participants design was used to examine component effects on treatment processes and outcomes in 15 adults seeking mental health treatment. The ACT OPEN module targeted acceptance and cognitive defusion; the ACT ENGAGED module targeted values-based activation and persistence. According to Tau-U analyses, both modules produced significant improvements in psychiatric symptoms, quality of life, and targeted therapeutic processes. ACT ENGAGED demonstrated greater improvements in quality of life and values-based activation. ACT OPEN showed greater improvements in symptom severity, acceptance, and defusion. Both modules improved awareness and non-reactivity, which were mutually targeted, though using distinct intervention procedures. Both interventions demonstrated high treatment acceptability, completion, and patient satisfaction. Treatment effects were maintained at 3-month follow up. ACT components should be considered for inclusion in a modular approach to implementing evidence-based psychosocial interventions for adults.

1. Introduction

The public health impact of evidence-based psychosocial interventions (EBPI) remains relatively low despite a proliferation of efficacious treatments for a wide range of behavioral and mental health problems (McHugh & Barlow, 2012; Wang et al., 2005). This science-practice gap may reflect a failure of the dominant intervention research paradigm to adequately address factors that influence the implementation of EBPI in usual care (Fairburn & Wilson, 2013; Kazdin & Blase, 2011; Rotheram-Borus, Swendsen, & Chorpita, 2012). Therapists report that they value the science behind EBPI, but are concerned that standardized manuals do not meet the needs of real-world clients and practice settings (Addis & Krasnow, 2000; Borntrager, Chorpita, Higa-McMillan, & Weisz, 2009; Nelson & Steele, 2007).

One promising approach to streamlining the translation of behavioral science to service is modularized treatment, which preserves the benefits of standardization inherent in manualized protocols, while allowing personalization through the use of algorithms for selecting treatment components. A recent randomized effectiveness trial for depression, anxiety, and conduct disorders in youth provides a compelling case example (Weisz et al., 2012). Modular treatment outperformed both standardized manual-based...
treatments and usual care in rate of clinical improvement and number of diagnoses at post-treatment (Chorpita et al., 2013), as well as number of service settings utilized one-year after treatment was initiated (Park et al., 2015). Modularization may further increase EBPI impact through improved therapist-mediated implementation outcomes. For example, therapists trained in a modular approach, versus a standard sequential manual, showed more favorable attitudes toward EBPI, a predictor of EBPI adoption (Borntrager et al., 2009). Additionally, therapists perceived modular treatments as more effective than usual care and more responsive than standard EBPI, contributing to significantly greater therapist satisfaction with modular treatment – an effect that grew as therapists gained more experience with modular treatment cases (Chorpita et al., 2015).

Acceptance and Commitment Therapy (ACT; Hayes, Strosahl, & Wilson, 1999, 2012) is a promising candidate for modularization because it is based on a transdiagnostic model that guides case formulation and selection of therapy tasks from a set of complementary treatment components, affording personalized treatment that is grounded in theory and evidence. ACT interventions are defined by their application of this psychological flexibility model, which specifies a set of modifiable processes involved in the development, maintenance, and amelioration of a broad range of problems in living (Hayes, Levin, Plumb-Vilardaga, Villatte, & Pistorello, 2013; Kashdan & Rottenberg, 2010). As opposed to transdiagnostic approaches that allow for individualized targeting of multiple disorders within a unified treatment protocol, ACT specifies a set of clinical competencies that are applied based on a functional assessment of psychological flexibility, regardless of diagnoses (Luoma, Hayes, & Walser, 2007). ACT treatment effects are partially or fully mediated by changes in these psychological processes (Hayes, Villatte, Levin, & Hildebrandt, 2011) and a recent meta-analysis of ACT component interventions reported medium to large effects on targeted outcomes for treatment procedures suggested by the psychological flexibility model (Levin, Hildebrandt, Lillis, & Hayes, 2012). Similarly, a recent process analysis showed that each 1-unit increase in smoking counselors’ use of procedures targeting certain ACT processes resulted in a 42–52% lower odds of smoking at subsequent counseling sessions (Vilardaga, Heffner, Mercer, & Bricker, 2014). Finally, many elements of the psychological flexibility model are shared by modern contextual therapies (Hayes et al., 2011) and traditional cognitive and behavior therapies (Arch & Craske, 2008; Hofmann & Asmundson, 2008), which could facilitate the adoption and integration of these components in a modular treatment approach.

The fact that a component is shared by multiple EBPs, however, is not sufficient to guide clinical decisions; an effective modular treatment depends on algorithms for selecting which components to implement in which situation (Chorpita, Daleiden, & Weisz, 2005a). This requires evidence of how component procedures impact therapy processes and outcomes, and how components function when removed from the treatment protocols tested in efficacy trials (Hayes et al., 2013; Rosen & Davison, 2003). Dismantling studies provide one method of acquiring this knowledge, but their feasibility is limited by the very large samples required to compare multiple components. Single case experimental designs (SCED) provide a pragmatic alternative that, when well-designed and executed, rival the scientific rigor of randomized controlled trials while requiring far fewer participants (Barlow, Nock, & Hersen, 2008; Smith, 2012; Vilardaga, 2014). Further, SCED have been used effectively in modular treatment development and evaluation (Chorpita, Taylor, Francis, Moffitt, & Austin, 2004), in part because many of these designs are analogous to clinical decision-making in a modular treatment approach.

The purpose of the current study was to examine the functional relationships between ACT intervention components, processes, and outcomes to inform the development of a modular, transdiagnostic treatment for adults. A randomized, nonconcurrent, multiple-baseline across participants design (N = 15) was used to examine the specificity of treatment effects for two ACT component modules; one targeting openness to thoughts, feelings, and sensations and the other emphasizing engagement in meaningful actions. These modules were examined in a sample of adults seeking treatment for depression and anxiety disorders. Visual and statistical analyses were employed to compare module effects on process and outcome measures across baseline, intervention, and follow-up phases. It was hypothesized that both interventions would produce improvements in psychiatric symptoms and quality of life, as well as in mutually targeted psychological processes. Group differences were expected in processes that were uniquely targeted by only one intervention module. Results of this proof-of-concept study will inform the development and evaluation of actuarial guidelines for selecting and implementing ACT components in a modular treatment design.

2. Method

2.1. Participants

Since ACT interventions target core processes that cross-cut psychiatric diagnoses, study inclusion was based on clinically significant psychological distress rather than diagnostic criteria. Participants were required to meet clinical case status (general severity index T score ≥ 63) on the Brief Symptom Inventory (Derogatis, 1993) and be 18 years or older. Individuals with active psychotic symptoms and those who could not read assessment measures written in English were excluded from study participation.

Participants were recruited through announcements in a community newspaper in northern-Nevada and 63 people were assessed by phone for study eligibility. Eighteen people met inclusion criteria and were invited to meet with an assessor for a 2-h clinical interview. The assessor confirmed eligibility, administered the Structured Clinical Interview Disorder for DSM-IV-TR Axis I Disorders (First, Spitzer, Gibbon, & Williams, 2002) for sample description purposes, and obtained demographic information and consent for participation. Three participants dropped out after in-dex assessment, but before random assignment, due to scheduling constraints. No participants refused participation after random assignment and all randomized participants (N = 15) were included in the main analyses.

Table 1 details participant demographics and diagnostic profiles at baseline. At time of enrollment, 67% were currently taking psychiatric medications. Of those 10 participants, 100% took one SSRI antidepressant, 13.3% took one benzodiazepine, and 6.7% took a stimulant. All participants denied medication changes during the study period. There were no statistically significant differences between treatment conditions on any demographic or diagnostic variables.

2.2. Design and treatment assignment

The study was designed to evaluate the specificity of ACT component effects on therapy processes and outcomes. A randomized, nonconcurrent, multiple-baseline across participants design was employed to ensure timely treatment delivery while minimizing threats to internal validity.

A randomized block design was used to ensure roughly equivalent numbers of participants per baseline length, therapist, and treatment module. Following enrollment, participants were
randomly allocated to an assessment-only baseline of 3, 4, or 5 weeks in fixed blocks of 3 using a computer random number generator. During baseline, participants received email reminders to complete weekly assessment packets and mail them to the assessor. Upon completion of baseline assessment, participants were allocated to therapist and intervention module in randomly varied blocks of 3–5 generated by a computer random number generator. Weekly assessments continued during the 8-week intervention phase following each treatment session. To increase study retention and reduce missing data, follow-up assessments were scheduled every four weeks for a total of three months. Participants received email reminders to complete monthly assessment packets and mail them to the assessor. In total, participants completed outcome and process measures at 14–16 time points, spanning baseline-, intervention-, and follow-up phases.

2.3. Interventions

2.3.1. ACT OPEN module

The ACT OPEN module consisted primarily of procedures targeting the acceptance and cognitive defusion processes of the psychological flexibility model, with the aim of reducing harmful responses to thoughts, feelings, and sensations. Early sessions explored clients’ conceptualizations of the presenting problem and therapists used metaphors and experiential exercises to orient clients to the short and long-term consequences of strategies they had employed to solve these problems. Throughout the module, therapists used language that fostered an open and curious stance toward psychological experiences and practiced non-evaluative awareness of thoughts, feelings, and sensations. Therapists introduced defusion strategies intended to evoke new responses to troublesome cognitions (e.g., thoughts are observed as if they are leaves floating on a stream). Defusion strategies were also employed to reduce the influence of self-concepts and beliefs that limit response flexibility.

2.3.2. ACT ENGAGED module

The ACT ENGAGED module consisted of procedures targeting the values and committed action processes of the psychological flexibility model, with the aim of increasing motivation and reinforcement for meaningful behaviors. Initial sessions explored personal values in order to instill a sense of purpose and direction. Therapists helped participants formulate their values as sources of satisfaction intrinsic to their own behavior, rather than as outcomes (e.g., achievement, praise) or in terms of negative reinforcement (e.g., escape from pain). Metaphors tailored to the client’s experience, such as that of a journey where purpose and meaning are found in each step and not only upon reaching one’s final destination, were used throughout the module to facilitate broadening and building behavioral repertoires and tracking contingencies that support valued action. Therapists used experiential exercises and language that oriented clients to their experience as a guide to effective action. For example, the metaphor of being guided by a compass versus a route on a roadmap oriented participants to the flexibility required to overcome obstacles and maintain a sense of direction when plans don’t proceed as expected. Therapists also employed behavioral commitment strategies to promote generalization and maintenance of valued action.

2.3.3. Module overlap

ACT’s psychological flexibility model specifies two additional change processes (i.e., contact with the present moment and a sense of self as the context or container of one’s experiences). These processes manifest themselves as a flexible self-awareness that allows one to experience distress without threat of psychological harm or annihilation, and to act intentionally, rather than reactively. Acting with awareness and intention are core targets in all ACT interventions and are considered essential to the treatment’s experiential approach to shaping in-session behavior in order to promote maintenance and generalization of treatment gains (Hayes et al., 2011). That is, a treatment that does not include procedures to facilitate fluid self-awareness would not be ACT-adherent. Accordingly, these two processes were engaged, though not emphasized, in both modules. However, each module targeted these processes using separate procedures that were completely distinct from the alternate treatment condition. For example, the ACT OPEN module employed meditation exercises designed to observe ongoing thoughts, feelings, and sensations without reacting to urges to change them. The ACT ENGAGED module did not include formal mindfulness exercises, but did train participants to be aware of their actions and the contexts in which they occur, so they could choose effective responses based on their personal values rather than react habitually. In summary, both modules targeted self-awareness processes, but there was zero overlap in

2.7.1. Cognitive defusion

In the current study, two-, and three-month follow-up. In the current study, changes in these domains, the WHOQOL was administered on only relationships, and living environment. Given the slower nature of quality of life related to physical and psychological health, social

2.6.2. Quality of life

The WHOQOL-BREF is a 26-item self-report inventory of psychological symptoms across nine domains and three global indices of distress. The global severity index of the BSI was used to measure psychological symptom severity, intensity, and number. In the current study, \( \alpha = .85 \).

2.8. Common change processes

2.8.1. Awareness

The Brief Symptom Inventory (BSI) was used to measure psychological symptom severity, intensity, and number. In the current study, \( \alpha = .85 \).

2.8.2. Nonreactivity

The Brief Symptom Inventory (BSI) was used to measure psychological symptom severity, intensity, and number. In the current study, \( \alpha = .85 \).

2.9. Analytic strategy

A bottom-up analytic approach (Onghena & Edgington, 2005; Parker & Vannest, 2012) was employed beginning with visual analysis to identify patterns within and across study phases, then proceeding to statistical analysis of individual phase contrasts within participants and across treatment conditions. Nonparametric Tau-U analyses were conducted to evaluate individual and aggregated effect sizes. This approach is free from assumptions of distribution and linearity, robust to serial dependence inherent in time-series designs, superior in power and precision over other SCED effect size indices, and allows for examination of changes in both mean levels and trend (Parker, Vannest, Davis, & Sauber, 2011).

For each participant, the percent of nonoverlap between all pairs
of data was calculated to determine baseline trend, intervention trend, mean contrasts between baseline and intervention phases, and combined trend and mean contrasts. Individual phase and participant contrasts were combined and weighted to provide an omnibus index of effect size per condition and p values were calculated using effect sizes and standard errors. Tau is analogous to the Pearson $r^2$ effect size, so it can be interpreted as the percent of the data variance accounted for by intervention effects.

3. Results

3.1. Treatment fidelity

Treatment fidelity was highly rated for both the ACT OPEN ($M = 4.53, SD = .05$) and ACT ENGAGED ($M = 4.72, SD = .04$) modules. No sessions were coded as employing procedures inconsistent with ACT or targeting a process purposefully omitted from the treatment module (i.e., no contamination). There were no statistically significant differences in fidelity between therapists, conditions, or sessions.

3.2. Treatment acceptance and completion

Participants were presented with a description and rationale for each treatment module prior to randomization. No participant refused treatment after being informed about the intervention to which they were randomly assigned. Both ACT modules demonstrated excellent retention, with all participants completing all 8 treatment sessions. Both modules were viewed as acceptable, with no session rated below 3 and an average score of 4.17 on the 5-point scale of the TEI. All 7 participants assigned to the ACT OPEN module rated the treatment with an average score of 4 or better, with 50% of sessions rated with the highest possible score. Seventy-five percent of the 8 participants assigned to the ACT ENGAGED module rated the treatment with an average score of 4 or better, with 40% of sessions given the maximum rating. These differences were not statistically significant, $t(12) = 1.73, p = .11$.

3.3. Treatment outcomes and processes

3.3.1. Visual analysis to inform statistical approach

The initial correlation matrix of study variables is reported in Table 2. Fig. 1 displays means and 95% confidence intervals for each of the outcome and process measures at each assessment point, by treatment condition. Visual inspection of the data detected no significant concerns about baseline trends, but baseline control was employed in Tau-U in order to be conservative in interpreting aggregated SCED results.

Visual analyses were consistent with previous studies suggesting ACT intervention trends carry-over into follow-up assessment phases (Luoma, Kohlenberg, Hayes, & Fletcher, 2012). This pattern is ideal from a clinical perspective, demonstrating that the intervention leads to ongoing improvement even after treatment ends. Tau analyses confirmed no statistically significant differences in omnibus (i.e., combined level and trend) effects between intervention and follow-up phases. Hence, data from these phases were collapsed for Tau-U analysis: within-subject tests compared data prior to intervention (phase A) with data during and following intervention (phase B).

Visual analysis identified consistent data patterns (both within and between phases) with two exceptions that have implications for statistical analysis. First, improvements on the Values Bullseye, though large, did not occur until the fourth week in the intervention phase for all participants in the ACT ENGAGED module, which targeted this process explicitly. It has been suggested that inclusion of such a lag in statistical analysis would not fairly represent the amount of change due to the intervention (Parkar & Vannest, 2012), so the first three weekly data points in the intervention phase were excluded from Tau-U analysis of the Values Bullseye.

The second aberrant pattern detected during visual inspection is that two participants receiving the ACT ENGAGED module displayed trends in opposite directions of their condition cohort (i.e., deterioration) on several measures. Exploratory analyses indicated that omission of the two outlying cases would not have affected the significance of any results; thus, they were retained in all final analyses. However, exploratory analyses of the nonresponders were conducted with the aim of identifying potential moderators to be explored in future studies. These results are reported in a separate section below.

3.3.2. Interpretation of statistical significance and effect sizes

Results of Tau-U analyses of within-subject treatment effects by treatment condition are reported in Table 3, while comparative effectiveness between the two intervention modules is reported in the text. Treatment effects are reported in terms of both level (i.e., percent of intervention and follow-up data showing improvement

Fig. 1. Means and 95% confidence intervals for outcome and process measures at each assessment point by treatment condition.
over baseline scores) and trend (i.e., percent of data showing improvement over previous intervention session). These effect sizes are transformed to a zero chance level and can be interpreted as small (0–31%), medium to large (32–84%), and very large (85–100%) effects (Parker & Vannest, 2009). An omnibus effect size combining level and trend improvements is also reported and can be interpreted as small (≤.30), medium (>.50), and large (>.80) effects (Parker et al., 2011). Probability values less than p = .005 were rounded to p = .00.

**Psychiatric symptom severity.** Both ACT modules showed clinically (i.e., no longer met threshold for clinical caseness) and statistically (p < .001) significant improvement on the BSI, though their effect sizes differed. The ACT OPEN module had a large effect on symptom severity, while the ACT ENGAGED module showed only moderate improvements. When examining omnibus treatment effects between conditions, participants who received the ACT OPEN module showed moderately greater reductions in symptom severity over those who received the ACT ENGAGED (Tau-U = .30, SE = .09, p = .00).

**Quality of life.** All participants reported large WHOQoL improvements over baseline and these gains were maintained across the three months of follow-up assessment. However, participants in the ACT ENGAGED condition showed moderately greater improvements over those in the ACT ENGAGED condition (Tau-U = .38, SE = .17, p = .02).

**Cognitive defusion.** All participants in the ACT OPEN condition, which exclusively targeted this process, made immediate and substantial session-by-session improvements in cognitive defusion. Participants in the ACT ENGAGED condition showed no changes in cognitive defusion. As predicted, the effects of the ACT OPEN module on this therapy process were significantly greater than the ACT ENGAGED module (Tau-U = .89, SE = .11, p = .00).

**Experiential Acceptance.** All participants who received the ACT OPEN module showed substantial improvement in acceptance, with moderately large session-by-session gains and almost no deterioration during the 3-month follow-up period. The ACT ENGAGED module, which did not target this treatment process, showed no changes in acceptance over time. As predicted, the ACT OPEN condition showed much greater improvements over the ACT ENGAGED condition (Tau-U = .89, SE = .11, p = .00).

**Values-based action.** This process was explicitly targeted only by the ACT ENGAGED module, which produced large improvements over baseline scores and reliable session-by-session growth in values-based action. Participants who received the ACT OPEN module demonstrated small improvements at follow-up relative to baseline scores on the Values Bullseye, though these improvements were not reliably linked to treatment trends and the omnibus treatment effect was not significant. The difference between modules was significant, with ACT ENGAGED demonstrating superior treatment effects (Tau-U = .54, SE = .10, p = .00).

**Awareness and Nonreactivity.** Both modules targeted the core ACT treatment processes of acting with awareness and intention, though they used different procedures to do so. Participants in both conditions showed large and steady treatment gains on the FFMQ-ACT Aware and FFMQ-Nonreact scales. Between-group analyses detected no significant differences by condition for awareness (Tau-U = .02, SE = .20, p = .83) or nonreactivity (Tau-U = .01, SE = .09, p = .93).

### 3.3.3. Exploratory nonresponder analyses

One male and one female within the ACT ENGAGED condition were identified as outliers compared to participants within and across treatment conditions. These two cases displayed no clinically significant improvements on any process or outcome measure. Compared to scores of other participants in the ACT ENGAGED condition, the two cases displayed 69% less improvement in quality of life (p = .04) and 68% less improvement in symptom severity (p = .00). These were the only cases in either condition to become more cognitively fused (Tau = .64, p = .00) and less accepting of thoughts and feelings (Tau = .56, p = .00), and to fail to show improvement in reactivity (Tau = .07, p = .71).

An analysis of participant characteristics at baseline revealed that the two nonresponsive cases were the only participants in the ACT ENGAGED condition to meet criteria for a current diagnosis of PTSD. These cases did not differ from participants in either condition at baseline on any demographic variable, number of past or current diagnoses, symptom severity, or any process measure. It is notable that the two participants in the ACT OPEN condition meeting criteria for a current PTSD diagnosis displayed patterns of improvement consistent with other participants within that treatment condition and showed no deterioration on process or outcome measures.

### 4. Discussion

The current study provides preliminary evidence supporting the inclusion of components of ACT’s psychological flexibility model in a modular transdiagnostic treatment that affords flexible use of techniques to target common core processes of therapeutic change. Both of the ACT component modules produced significant

Note. Improvement over baseline and session by session improvement can be interpreted as small effects (0–31%), medium to large effects (32–84%), and very large effects (85–100%); Omnibus effect size = combined level and trend improvements, with small effect = .20, medium effect = .50, large effect = .80.

improvements in symptom severity and quality of life, but at different rates and magnitudes and using different techniques. The ACT OPEN module, which targeted acceptance and cognitive defusion processes, produced greater session-by-session improvement and larger overall reductions in symptom severity. In spite of its smaller effect on symptoms, the ACT ENGAGED module, which targeted values-based activation and behavioral commitment processes, produced greater quality of life improvements. This result is consistent with ACT’s psychological flexibility model, which makes a distinction between symptom reduction and well-being (Hayes et al., 2013).

Each ACT module produced sustained changes in the psychological processes that were uniquely and explicitly targeted by that component. Large improvements in acceptance and defusion were observed in the ACT OPEN condition, while these processes remained unchanged in the ACT ENGAGED condition. It is interesting to note that moderate symptom reduction and large quality of life improvements occurred even though judgment and believability of negative thoughts remained high in this condition. Conversely, the ACT ENGAGED module produced a 73% improvement in values-based behavior, which was the emphasis of this component intervention. Though the ACT OPEN component did not directly target values and commitment processes, it appears that some participants in this condition independently brought their behaviors into greater alignment with their personal values after learning to relate differently to their thoughts and feelings. Component interventions that produce these types of rapid, simultaneous improvements across multiple areas of functioning should be prioritized when considering common elements for inclusion in modular treatments.

Nonreactive awareness of one’s self and environment is a central feature of the psychological flexibility model and a common core element in all ACT interventions. Both ACT modules produced improvements in the awareness and nonreactivity facets of mindfulness, though by different means. The ACT ENGAGED module included procedures to help participants discover sources of inspiration and satisfaction in their own behavior and to intentionally choose responses with a purpose. Procedures in the ACT OPEN module helped participants maintain open awareness of their thoughts and feelings without attempting to alter their experience. Thus, different treatment techniques can be used to impact the same processes of change, allowing therapists the flexibility to adapt interventions for specific clients while maintaining fidelity to an evidence-based treatment model.

An effective personalized treatment relies on an understanding of patient characteristics that influence intervention processes and outcomes. Exploratory analyses of outlying cases revealed that participants in the ACT ENGAGED condition with a current diagnosis of PTSD showed no improvement or deterioration on several outcome and process measures. This pattern was inconsistent with all other study participants, including those in the ACT OPEN condition with a current PTSD diagnosis. This is insufficient evidence to draw conclusions about implementing these modules with PTSD patients, but the independent, additive, and order effects of acceptance and values interventions warrant further examination in this population.

It is possible that modules targeting acceptance and defusion may be necessary precursors to modules aimed at values-based behavioral activation for individuals with a current PTSD diagnosis. In a case study of ACT for treatment-resistant PTSD, Twohig (2009) found that values interventions were not tolerated until 6 sessions of acceptance, cognitive defusion, and self-as-context interventions (roughly equivalent to the current ACT OPEN module) were completed. Similarly, improvements in the FFMQ facets of nonjudgment and nonreactivity to inner experiences explained 19–24% of the variance in depression and PTSD outcomes in a residential CBT treatment for PTSD (Boden et al., 2012). In the current study, clients with PTSD in the ACT ENGAGED condition were the only study participants who did not show improvements on these measures. Future experimental studies should examine the impact of acceptance and values components and processes, in isolation and combination, in adults with PTSD.

4.1. Implications for modular treatment development, dissemination, and implementation

Therapists cannot be expected to learn each new treatment package supported by a randomized controlled trial, particularly when many EBPs share core components and target similar psychological processes, making distinct training in complete treatment packages potentially redundant and unnecessary (Chorpita et al., 2011). A modular approach that provides training and guidelines for implementing evidence-based components, rather than session-by-session protocols organized by diagnosis, is a promising solution to known implementation barriers. The modular approach capitalizes on therapists’ tendency to be integrative when adapting efficacious treatments to real-world practice demands. Modular treatments are efficient to train, inherently flexible, and easy to update as new intervention data emerges. Modularity is also an ideal fit with current trends toward disruptive innovations in EBPs, as it is patient-centered, responsive to idiographic variables that influence treatment engagement and response, and maintains a tight link to the evidence base while allowing therapists to select components that match their expertise and are feasible within their practice settings (Rotheram-Borus et al., 2012).

The contextual behavioral scientific approach that gave rise to ACT (Hayes et al., 2013) is well-suited to modular treatment design and evaluation because both rest on a pragmatic philosophy that lends itself to inductive and iterative methodologies for knowledge development and dissemination. Single case experimental designs are ideal for this kind of treatment distillation and matching because they allow for rapid knowledge generation based on critical comparisons at the level of clinical decision-making. Meta-analyses of between-group treatment effects, including additive and dismantling studies, are unlikely to yield actionable insights for EBPI implementers (e.g., Ahn & Wampold, 2001; Bell, Marcus, & Goodlad, 2013) due to mismatched levels of analysis that obscure potentially important treatment by context interactions (for an illustrative exception, see Weisz, Weiss, Aliche, & Klotz, 1987). The current study employed aggregated single case experiments to test functional relationships among procedures, processes, and outcomes in two trandiagnostic content modules (Chorpita, Daleiden, & Weisz, 2005b), which serve as the building blocks in modular treatment design. This methodology could also be employed in the development and evaluation of coordination modules, which outline the algorithms for deciding when to use which content modules and would constitute the next step in modular treatment development.

The current study does not test a modular treatment protocol, but it does test key properties of proposed treatment modules, defined as “self-contained functional units that connect with other units, but do not rely on those other units for their own stable operations” (Chorpita et al., 2005b, p. 142). The principle of proper functioning signifies that modules are defined by their function, not by categorical labels (e.g., ACT) or techniques (e.g., meditation), and must demonstrate reliable production of intended results in terms of therapeutic processes (e.g., emotional acceptance) and outcomes (e.g., symptom severity, quality of life). This study demonstrated...
the proper functioning of ACT OPEN and ACT ENGAGED modules in both specific and common treatment processes and outcomes. The principle of encapsulation refers to keeping all knowledge and competencies necessary for successful implementation of each module self-contained, allowing maximal flexibility in selecting and sequencing modules. Fidelity monitoring within the current study demonstrated that ACT modules can be functionally independent and distinct, adequately addressing a wide range of clinical content across 8 sessions with no contamination of therapy procedures across modules or use of procedures not specified by the module (e.g., non-adherence).

The current study suggests that treatment modules targeting components of ACT’s psychological flexibility model are feasible and effective in treating adults with mixed anxiety and depression. Both the ACT OPEN and ACT ENGAGED modules were acceptable to adults seeking mental health treatment, demonstrating 100% treatment completion rates and very high levels of patient satisfaction post-treatment and at 3-month follow-up. Both modules demonstrated broad symptom improvements and sustained increases in quality of life, though they were comprised of wholly different interventions and produced distinct changes in psychological processes. Components such as these afford therapists flexibility in developing a treatment that is both personalized and pragmatic, while maintaining its link to the evidence base.

4.2. Limitations and recommendations for future research

Though the present study design provided a good balance between external validity and experimental control (e.g., randomization, replication across participants), critical comparisons should be replicated to see if current results hold across experimenters, treatment settings, therapists, and participants. While formal mediation analyses were beyond the scope of the current study, examination of time-lagged associations between process and outcome variables are possible within single case experiments (Hilliard, 1993; Tschacher & Ramseyer, 2009) and are recommended for developing modular treatment protocols that optimize exposure to key treatment mechanisms.

It will also be important to further assess how participant, therapist, and setting variables interact with modular treatment components. Future studies should examine module dependencies, including order and additive effects, and specific person X module X context interactions in order to develop testable clinical decision algorithms and coordination modules. Though group designs would require massive samples to power so many interaction effects, results from SCED, including the current study, can be aggregated to provide guidelines for personalized selection and evaluation of treatment components (Van den Noortgate & Onghena, 2007). While the majority of published meta-analyses compare group means and yield only a single estimate of an intervention effect (Alemayehu, 2011), meta-analyses of the rich individual-level data from single case experiments can provide detailed knowledge of individual patient, therapist, and context variables that influence treatment effectiveness (Cooper & Patall, 2009; Iwakabe & Gazzola, 2009; Thompson & Higgins, 2005).

Such a progressive accumulation of “big data” may finally allow us to answer Gordon Paul’s (Paul, 1969) ultimate clinical question of “what treatment, by whom, is most effective for this individual with that specific problem, under which set of circumstances, and how does it come about?”
